Obese diet-induced mouse models of nonalcoholic steatohepatitis-tracking disease by liver biopsy

Maria Nicoline Baandrup Kristiansen, Sanne Skovgård Veidal, Kristoffer Tobias Gustav Rigbolt, Kirstine Sloth Tølbøl, Jonathan David Roth, Jacob Jelsing, Niels Vrang, Michael Feigh

AIM: To characterize development of diet-induced nonalcoholic steatohepatitis (NASH) by performing liver biopsy in wild-type and genetically obese mice.

METHODS: Male wild-type C57BL/6J (C57) mice (DIO-NASH) and male Lep"ob/Lep"ob (ob/ob) mice (ob/ob-NASH) were maintained on a diet high in trans-fat (40%), fructose (22%) and cholesterol (2%) for 26 and 12 wk, respectively. A normal chow diet served as control in C57 mice (lean chow) and ob/ob mice (ob/ob chow). After the diet-induction period, mice were liver biopsied and a blinded histological assessment of steatosis and fibrosis was conducted. Mice were then stratified into groups counterbalanced for steatosis score and fibrosis stage and continued on diet and to receive daily PO dosing of vehicle for 8 wk. Global gene expression in liver tissue was assessed by RNA sequencing and bioinformatics. Metabolic parameters, plasma liver enzymes and lipids (total cholesterol, triglycerides) as well as hepatic lipids and collagen content were measured by biochemical analysis. Non-alcoholic fatty liver disease activity score (NAS) (steatosis/inflammation/ballooning

Abstract

AIM: To characterize development of diet-induced nonalcoholic steatohepatitis (NASH) by performing liver biopsy in wild-type and genetically obese mice.

METHODS: Male wild-type C57BL/6J (C57) mice (DIO-NASH) and male Lep"ob/Lep"ob (ob/ob) mice (ob/ob-NASH) were maintained on a diet high in trans-fat (40%), fructose (22%) and cholesterol (2%) for 26 and 12 wk, respectively. A normal chow diet served as control in C57 mice (lean chow) and ob/ob mice (ob/ob chow). After the diet-induction period, mice were liver biopsied and a blinded histological assessment of steatosis and fibrosis was conducted. Mice were then stratified into groups counterbalanced for steatosis score and fibrosis stage and continued on diet and to receive daily PO dosing of vehicle for 8 wk. Global gene expression in liver tissue was assessed by RNA sequencing and bioinformatics. Metabolic parameters, plasma liver enzymes and lipids (total cholesterol, triglycerides) as well as hepatic lipids and collagen content were measured by biochemical analysis. Non-alcoholic fatty liver disease activity score (NAS) (steatosis/inflammation/ballooning
RESULTS: Diet-induction for 26 and 12 wk in DIO-NASH and ob/ob-NASH mice, respectively, elicited progressive metabolic perturbations characterized by increased adiposity, total cholesterol and elevated plasma liver enzymes. The diet also induced clear histological features of NASH including hepatosteatosis and fibrosis. Overall, the metabolic NASH phenotype was more pronounced in ob/ob-NASH vs DIO-NASH mice. During the eight week repeated vehicle dosing period, the metabolic phenotype was sustained in DIO-NASH and ob/ob-NASH mice in conjunction with hepatomegaly and increased hepatic lipids and collagen accumulation. Histopathological scoring demonstrated significantly increased NAS of DIO-NASH mice (0 vs 4.7 ± 0.4, P < 0.001 compared to lean chow) and ob/ob-NASH mice (2.4 ± 0.3 vs 6.3 ± 0.2, P < 0.001 compared to ob/ob chow), respectively. Furthermore, fibrosis stage was significantly elevated for DIO-NASH mice (0 vs 1.2 ± 0.2, P < 0.05 compared to lean chow) and ob/ob NASH (0.1 ± 0.1 vs 3.0 ± 0.2, P < 0.001 compared to ob/ob chow). Notably, fibrosis stage was significantly (P < 0.001) increased in ob/ob-NASH mice, when compared to DIO-NASH mice.

CONCLUSION: These data introduce the obese diet-induced DIO-NASH and ob/ob-NASH mouse models with biopsy-confirmed individual disease staging as a preclinical platform for evaluation of novel NASH therapeutics.

Key words: Nonalcoholic steatohepatitis; Liver biopsy; Diet-induced obesity; Nonalcoholic fatty liver disease; Fibrosis

Core tip: We characterize the development and progression of diet-induced nonalcoholic steatohepatitis (NASH) in a wild-type and a genetically obese mouse model. We confirm that a diet high in trans-fat, fructose and cholesterol, develops key histological hallmarks of NASH (steatosis, inflammation, ballooning degeneration) in conjunction with fibrosis. Concomitantly, marked alterations in NASH associated gene expression pathways can be evaluated by RNaseq analysis. In addition, we describe that performing a baseline liver biopsy enables individual disease staging for subsequent stratified randomization of animals into study groups. Finally, we show these models’ utility for a chronic repeated dosing study to evaluate pharmacological intervention.

INTRODUCTION

It is generally accepted that along with increasing rates of obesity, type 2 diabetes and metabolic syndrome, the incidence and prevalence of patients with nonalcoholic fatty liver disease (NAFLD) continues to rise[1-4]. NAFLD is considered the hepatic manifestation of the metabolic syndrome and covers a variety of pathologies ranging from simple hepatic steatosis (accumulation of triglycerides in hepatocytes) to nonalcoholic steatohepatitis (NASH), characterized by inflammation, cellular ballooning and fibrosis in varying degrees[5-3]. The pathogenesis of NASH is described by the "two-hit" hypothesis, the first hit being fat accumulation in hepatocytes, while the "second hit", e.g., oxidative stress, apoptosis or mitochondrial dysfunction, causes development of inflammation and fibrosis[6].

There are currently no pharmacological agents specifically approved for the treatment of NASH and disease management is consequently focused on the correction of underlying risk factors (e.g., obesity, insulin resistance and dyslipidemia)[4,5]. A likely contributor to the absence of therapeutics is the paucity of preclinical models resembling human NAFLD/NASH[5]. Historically, several animal models have been developed to represent the pathophysiology, morphological findings, biochemical changes, and clinical features of human NAFLD/NASH. These models are usually divided into two main categories: The diet-induced models and the genetically modified models (transgenic or knockout models)[6]. Some diet-induced models are based on ad libitum feeding of diets enriched with various combinations of fat, cholesterol and sugars (e.g., fructose) thereby developing a metabolic phenotype reflected by adiposity and hepatosteatosis, albeit only presenting mild characteristics of NASH and typically lack of liver fibrosis[7,8]. Other dietary models involve feeding nutrient-deficient diets such as the methionine- and choline-deficient diet (MCD). Methionine and choline deficiency impairs liver β-oxidation and the production of very-low density lipoproteins (VLDL) hereby generating a "second hit"[9], eliciting a more severe fibrotic NASH phenotype within hepatic tissue[10]. However, these models fail to recapitulate a clinically relevant overall metabolic phenotype as MCD animals demonstrate pronounced weight loss and perturbed energy- and glucose homeostasis[10]. Recently, a novel wild-type diet-induced obese fibrotic NASH mouse model was introduced by Trevaskis et al[11], based on the AILOS diet model[12]. This model, generated by feeding an ad libitum diet high in trans-fat, fructose and cholesterol to wild-type C57Bl/6J mice (the Amylin liver NASH model [AMLN], displayed key hallmarks of clinical NASH[11]). The AMLN mouse model was further optimized by demonstrating a liver biopsy technique for

assessing individual steatosis, inflammation, ballooning degeneration and fibrosis staging, prior to a putative study intervention\(^6\). Not only does the baseline liver biopsy reduce biological variability by excluding mice that fail to develop NASH prior to initiating therapy, but it also allows for within-subject comparisons over time, thereby increasing statistical power\(^6\).

For the genetically modified NASH models, several studies have implicated a role of individual genes involved in the development of NASH using deletion or overexpression models\(^7,9\). For example, mice that overexpress the transcription factor sterol regulatory element-binding proteins (SREBPs), a feedback regulatory system controlling intracellular levels of cholesterol and free fatty acids develop a hepatic phenotype resembling NASH. However, like MCD-fed mice, SREBP overexpression does not induce a metabolic profile consistent with obesity and insulin resistance\(^13\). In contrast, impairment of leptin signaling (e.g., db/db mice) results in obesity, insulin resistance and diabetes\(^14\). Leptin-deficient mice (Lep\(^{-/-}\)/Lep\(^{-/-}\)) are predisposed to develop steatohepatitis, however, when maintained on regular rodent chow they do not develop fibrosis\(^11\). In fact, it was previously postulated that Lep\(^{-/-}\)/Lep\(^{-/-}\) mice are incapable of developing hepatic fibrosis\(^9\). This notion was dispelled by the observation that Lep\(^{-/-}\)/Lep\(^{-/-}\) mice maintained on the AMLN diet for at least 12 wk do in fact develop the key hallmarks of NASH, including fibrosis\(^11\).

The present study assessed key NASH diagnostic characteristics (e.g., steatosis score, inflammation, ballooning degeneration and fibrosis stage), metabolic endpoints and gene expression signatures in wild-type C57Bl/6J and Lep\(^{-/-}\)/Lep\(^{-/-}\) mice, fed the AMLN diet for a total of 34 and 20 wk, respectively, including an eight-week repeated vehicle dosing period. In addition, we demonstrate how a baseline liver biopsy allows for individual disease staging and for stratified randomization into experimental groups with reduced biological variability and for a clear cut analysis of individual response to pharmacological intervention.

**MATERIALS AND METHODS**

**Animals and experimental set-up**

All animal experiments were conformed to international accepted principles for the care and use of laboratory animals and were covered by a personal license for Jacob Jelsing (2013-15-2934-00784) issued by the Danish Committee for animal research.

Male C57Bl/6J (C57) and Lep\(^{-/-}\)/Lep\(^{-/-}\) (ob/ob) mice at 5 wk of age were obtained from JanVier (JanVier labs, France), and group housed 5 animals per cage under a 12/12 h dark-light cycle. Room temperature was controlled to 22 ± 1 °C, with 50% ± 10% humidity. Animals had ad libitum access to diet high in fat (40%, of these 18% trans-fat), 40% carbohydrates (20% fructose) and 2% cholesterol (D09100301, Research Diet, United States) previously described as the AMLN diet\(^6\), or regular rodent chow (Altromin 1324, Brogaarden, Denmark), and tap water. Both strains had ad libitum access to either the AMLN diet (DIO-NASH, n = 110; ob/ob NASH, n = 40) or chow (lean chow, n = 10; ob/ob chow, n = 10). After 26 (DIO-NASH) or 12 wk (ob/ob-NASH) a liver biopsy was performed for histological assessment of individual fibrosis and steatosis staging at baseline. Following biopsy procedure animals were single housed. An 8-wk vehicle intervention period was conducted in a representative subset of DIO-NASH and ob/ob-NASH mice, and their respective chow controls. Vehicle dosing consisted of once daily per oral dose of carboxymethyl cellulose (CS7 and ob/ob) and subcutaneous injection with PBS (C57). The rationale was to mimic repeated dosing administration and animal handling in combination with AMLN diet-maintenance. After a total of 34 and 20 wk on AMLN diet for DIO-NASH and ob/ob-NASH mice, respectively, animals were euthanized and liver tissue collected for histological and biochemical analysis. Total animal numbers for each experiment is indicated in the figures and table.

**Baseline liver biopsy after diet-induction**

Mice were pretreated with enrofloxacin (Bayer, Germany) (5 mg/mL-1 mL/kg) one day before being biopsied. Prior to biopsy, mice were anesthetized with isoflurane (2%-3%) in 100% oxygen. A small abdominal incision in the midline was made and the left lateral lobe of the liver was exposed. A cone shaped wedge of liver tissue (50-100 mg) was excised from the distal portion of the lobe fixed in 4% paraformaldehyde for histology. The biopsy procedure previously described by Clapper et al\(^8\), 2013 was refined using electrocoagulation of the cut surface of the liver by means of bipolar coagulation using ERBE VIO 100C electrosurgical unit (ERBE, United States). The liver was returned to the abdominal cavity, abdominal wall was sutured and skin stapled. Carprofen (Pfizer, United States) (5 mg/mL-0.01 mL/10 g) and enrofloxacin (5 mg/mL-1 mL/kg) were administered intraperitoneal at the time of surgery and at post-operation day one and two, to control postoperative pain relief and infection, respectively.

**Hepatic gene expression changes**

Gene expression changes were measured in a representative subset of DIO-NASH mice and ob/ob-NASH. Liver tissue was harvested from the left lateral lobe and snap frozen in liquid nitrogen. Tissue sections (about 50 mg) were homogenized in lysis buffer containing protease inhibitors and used for RNA extraction using NucleoSpin Plus RNA columns (Macherey-Nagel). The quantity of the RNA was analyzed using a Nano Drop 2000 spectrophotometer (Thermo Scientific, United States). RNaseq libraries were prepared with the KAPA poly-A kit (Kapa Biosystems, United States) and sequenced on the NextSeq 500 (Illumina, United States) (single-end, 75 bp reads). Reads were aligned to the GRCm38 Ensembl Mus musculus genome using STAR v.2.4.0\(^15\) and feature counts were obtained using HTSeq v.0.6.1\(^16\), both with default parameters. Differential
expression analysis was performed with edgeR\textsuperscript{[17]} and genes with a $P \leq 0.05$ after correction for multiple testing using the Benjamini and Hochberg method was regarded as significantly regulated. Pathway analysis of WikiPathways\textsuperscript{[18]} was performed using the statistics module in PathVisio\textsuperscript{[19]}.

**Body weight and body composition analysis**

Body weight was intermittently monitored during the diet-induction period and once daily during the intervention period. Whole-body fat mass was analyzed at baseline (week -1) and week 8 of the intervention period by non-invasive EchoMRI scanning using Echo-MRI-900 (EchoMRI, United States). During the scanning procedure the mice were placed in a restrainer for 90-120 s.

**Plasma biochemistry analysis**

After diet-induction, a baseline blood sample was collected from the submandibular vein in non-fasted conscious animals and blood sampling was repeated following the intervention period. Plasma levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), triglycerides (TG) and total cholesterol (TC) were measured using the auto analyzer Cobas C-111 (Roche Diagnostics, Germany). Plasma levels of insulin were measured in duplicates using an AlphaLisa kit (Perkin Elmer), according to the manufacturer’s instructions.

**Oral glucose tolerance test**

An oral glucose tolerance test (OGTT) was performed in week 4 of the intervention period. Animals were fasted for 4 h prior to OGTT. At $t = 0$ an oral glucose load [2 g/kg glucose 200 mg/mL, (Fresenius Kabi, Sweden)] was administered via a gastrically placed tube. Blood samples for measuring blood glucose (BG) were collected from the tail vein at $t = 0, 15, 30, 60$ and 120 min. Glucose area under the curve (AUC) calculations were determined as total AUC from the sampling period of 0 to 120 min.

**Whole blood glucose analysis**

Blood samples for BG analysis were collected into 10 µL heparinized glass capillary tubes and immediately suspended in buffer [0.5 mL of glucose/lactate system solution (EKF-diagnostics, Germany)] and analyzed for glucose using a BIOSEN c-Line glucose meter (EKF-diagnostics, Germany) according to the manufacturer’s instructions.

**Terminal hepatic hydroxyproline content**

Formalin fixed (50 mg) liver tissue was homogenized in 500 µL water. Five hundred microliter concentrated HCl was added to the samples and hydrolyzed at 120 °C for three hours. Supernatants were transferred to a 96 well plate and wells were allowed to evaporate dry overnight. Total collagen content in the liver was measured by colorimetric determination of hydroxyproline residues by acid hydrolysis of collagen (Cat no. MAK008, Sigma Aldrich).

**Terminal hepatic triglyceride and total cholesterol content**

A liver piece (about 100 mg) was collected in FastPrep tubes and snap-frozen in liquid nitrogen. One milliliter 5%NH-40/ddH$_2$O solution (ab142227, Abcam) was added to the FastPrep tube. The tubes were homogenized in a FastPrep homogenizer and shaken for 2 x 60 s. After homogenization the samples were slowly heated to 80°C-100°C in a heating block for three minutes. Samples were allowed to return to room temperature prior to a second round of heating. Next, samples were centrifuged for two minutes at top speed using a microcentrifuge to remove any insoluble material. TG and TC content in liver homogenates are measured in single determinations using auto analyzer Cobas C-111 with commercial kit (Roche Diagnostics, Germany) according to manufacturer’s instructions.

**Histology assessment and digital image analysis**

Baseline liver biopsy and terminal samples were collected from the left lateral lobe (about 100 mg) and fixed overnight in 4% paraformaldehyde. Liver tissue was paraffin embedded and sectioned (3 µm thickness). To assess hepatic morphology and fibrosis, sections were stained with Hematoxylin and Eosin and Sirius Red, respectively, followed by analysis with Visiopharm software (Visiopharm, Denmark). Histological assessment and scoring was performed by a pathologist blinded to the study. NAFLD activity score (NAS) (steatosis/ inflammation/ballooning degeneration) and fibrosis stage were performed using the clinical criteria outlined by Kleiner et al\textsuperscript{[20]}.

**Statistical analysis**

All data were analyzed using GraphPad Prism 5.0. The results are presented as mean ± standard error of the mean. Statistical significance was evaluated using One-way analysis of variance with Turkey’s multiple comparison test, and for histological analysis using Kruskal-Wallis test with Dunn’s multiple comparison test. $P < 0.05$ was considered statistically significant.

**RESULTS**

**Male C57 and ob/ob mice developed adiposity and elevated plasma metabolic parameters after AMLN diet-induction**

The overall study design is outlined in Figure 1A. Following a diet-induction period of 26 wk, C57 (DIO-NASH) mice demonstrated increased body weight (adiposity), when compared to lean chow animals. In the already obese ob/ob strain there was no additional effect on body weight noted in ob/ob–NASH mice relative to chow controls. Whereas all mice experienced slight weight loss following the biopsy, they returned
to a weight stable state within one week (Figure 1B). After diet-induction, DIO-NASH and ob/ob-NASH mice demonstrated a metabolic NAFLD phenotype, as reflected by elevated levels of plasma total cholesterol (TC) and liver enzymes ALT and AST, when compared to respective chow fed animals. Overall, the ob/ob-NASH mice demonstrated an accelerated and more pronounced metabolic phenotype, when compared to DIO-NASH mice (Table 1).

**Male C57 and ob/ob mice demonstrated biopsy-proven hepatic steatosis and fibrosis after AMLN diet-induction**

Histological assessments of biopsied liver tissue revealed that lean chow animals did not develop hepatic steatosis or fibrosis over the 26-wk diet-induction (Figure 1C and D). In contrast, DIO-NASH mice presented with high levels of steatosis (score 3) (Figure 1C) and fibrosis stage ranging from 1-3 (Figure 1D). The ob/ob chow phenotype displayed mild steatosis (score 1-2) and lack of or only mild fibrosis (stage 1) whereas all ob/ob-NASH mice displayed a steatosis score of 3 (Figure 1C) and a fibrosis stage ranging from 1-4 (Figure 1D).

**Altered hepatic gene expression in male C57 and ob/ob mice after AMLN diet-induction**

To characterize the effect of 26 wk diet-induction on global liver gene expression, the transcriptome of lean chow vs DIO-NASH mice were analyzed by RNAseq. Principal component analysis identified a clear separation between the two groups along the first component,
indicating that the NASH diet markedly alters the overall gene expression profile (Figure 2A). We identified a total of 1378 differentially expressed genes, composed of 510 repressed and 868 induced genes (Figure 2B). To explore biological processes affected, sets of significantly altered signaling pathways were extracted (Figure 2C and D). Many of these pathways are consistent with the observed NASH phenotype including focal adhesion, toll-like receptor (TLR) signaling pathway, matrix metalloproteinases and inflammatory response pathway. Consistent with the identification of focal adhesion as the top affected pathways multiple collagen subtypes showed increased expression (Figure 2E).

Similar analyses were conducted on a subset of samples from ob/ob-NASH animals which confirmed the exaggerated expression levels of collagen types (Figure 2E). The pathway analysis also highlighted TLR signaling as one of the primary affected signaling processes, an observation supported by the increased expression of TLR4, which was recently demonstrated as an important pro-inflammatory mediator in the pathogenesis of NASH.[22,23] Notably, mRNA expression levels of a number of other TLR subtypes (TLR7, TLR8, TLR12 and TLR13) were upregulated to greater extent than TLR4 (Figure 2F). Furthermore, a large collection of pro-inflammatory factors ranging from chemokines, such as monocyte chemoattractant protein-1 (MCP-1), to chemokine receptors, such as C-C motif chemokine receptor-2 (Ccr2) and macrophage markers (i.e., CD68, CD86, F4-80 and MAC-2) (Figure 2G) were significantly induced. Finally, in line with observed hepatosteatosis, expression levels of genes involved in triglyceride biosynthesis were significantly increased in C57 and ob/ob animals exposed to the AMLN diet. Conversely, cholesterol biosynthesis expression was significantly decreased in the DIO-NASH and ob/ob-NASH mice (Figure 2H).

**Male C57 and ob/ob mice sustained adiposity and elevated plasma metabolic parameters after AMLN diet-maintenance and repeated dosing intervention period**

During the intervention period with diet-maintenance and repeated vehicle dosing for a total of 8 wk, DIONASH mice progressively gained body weight (adiposity), when compared to lean chow animals. Leptin-deficient mice also gained fat mass during the 8-wk intervention period (Figure 1E and F). Fat gain was somewhat less in the ob/ob-NASH mice, however, these mice began the study with a higher % adiposity (37%, n = 10) relative to DIO-NASH mice (14%, n = 12). At study end (termination), DIO-NASH and ob/ob-NASH animals sustained the elevated levels of plasma liver enzymes and hypercholesterolemia, when compared to respective chow-fed mice (Table 1). In contrast, terminal plasma TG levels were unchanged in DIO-NASH mice, and were significantly decreased for ob/ob-NASH animals,

NASH: Nonalcoholic steatohepatitis; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BW: Body weight; OGTt: Oral glucose tolerance test; AUC: Area under the curve.
when compared to chow (Table 1). Collectively, terminal plasma levels of ALT, AST and TC were markedly elevated in ob/ob-NASH, when compared to DIO-NASH mice (Table 1).

An OGTT was performed four weeks into the intervention period. Fasting blood glucose and OGTT AUC for blood glucose were unchanged in DIO-NASH and ob/ob-NASH mice, as compared to respective chow fed animals (Table 1). Diet effects on glycemic status are supported by the elevation in plasma insulin levels of about 3-fold (NS) in DIO-NASH when compared to lean chow, whereas ob/ob-NASH showed a surprisingly decrease in plasma insulin levels at study end when compared to ob/ob chow animals (Table 1).

Male C57 and ob/ob mice demonstrated hepatomegaly with increased hepatic lipids and collagen content after AMLN diet-maintenance and repeated dosing intervention period

At study end, terminal liver weight was significantly increased in DIO-NASH and ob/ob-NASH mice, when compared to respective chow animals (Figure 3A). Additionally, liver weight of ob/ob-NASH was significantly higher than liver weight of DIO-NASH animals (Figure 3A). Both strains demonstrated increased deposition of liver TG and TC when compared to respective chow mice.
Liver TG and TC content were significantly increased in ob/ob-NASH mice, when compared to DIO-NASH animals (Figure 3B and C). Notably, DIO-NASH and ob/ob-NASH mice showed elevated levels of liver hydroxyproline (collagen) content, when compared to chow controls (Figure 3D). Overall, levels of liver hydroxyproline content were higher in ob/ob-NASH animals relative to DIO-NASH mice (Figure 3D).

Histopathological scoring of liver steatosis, inflammation and ballooning degeneration after AMLN diet-maintenance and repeated dosing intervention period in male C57 and ob/ob mice

Blinded histological assessment of NAS was performed on hematoxylin and eosin stained terminal hepatic tissue (Table 1). No evidence of steatosis, inflammation and ballooning degeneration was observed in lean chow controls (Figure 4A). In ob/ob chow mice steatosis was categorized as pronounced microvesicular with mild microvesicular steatosis (Figure 4B). Despite increased steatosis when maintained on chow diet, neither ballooning degeneration nor inflammation was observed in ob/ob chow animals (Figure 4B). In contrast, DIO-NASH mice developed micro- and macro-vesicular steatosis, with inflammation and ballooning degeneration (Figure 4C). Similarly, ob/ob-NASH mice developed micro- and macro-vesicular steatosis, and more pronounced inflammation and ballooning degeneration (Figure 4D). Thus, the NAS phenotypes of both strains of mice were clearly reflected in significantly increased NAS, when compared to respective chow animals (Figure 4E).

Histopathological scoring of liver fibrosis after AMLN diet-maintenance and repeated dosing intervention period in male C57 and ob/ob mice

Fibrosis stage was assessed by blinded histological evaluation using Sirius red staining of terminal liver tissue (Table 1). Hepatic fibrosis was not observed in lean chow or ob/ob chow mice (Figure 5A and B). In contrast, fibrosis was observed in DIO-NASH mice (Figure 5C) and to a greater extent in ob/ob-NASH animals who progressed to bridging fibrosis (Figure 5D). Fibrosis was most evident at tissue margins, but also penetrated into the tissue (Figure 5A-D). The fibrotic phenotypes of the DIO-NASH and ob/ob-NASH mice were mirrored by an increase in fibrosis stage compared to respective chow animals (Figure 5E). Increases in fibrosis stage were reflected by our image analyses showing an increase in % fractional area of Sirius Red (Figure 5F). Notably, the ob/ob-NASH animals were more fibrotic than DIO-NASH mice (Figure 5E and F).

DISCUSSION

In the present study two obese mouse models of diet-induced NASH were evaluated; the C57 DIO-NASH and the ob/ob-NASH. We confirm that a diet high in trans-fat, fructose and cholesterol produces a metabolic NASH phenotype with elevated plasma liver enzymes,
hepatomegaly and recapitulates multiple clinical features including key hallmarks of NASH (steatosis, inflammation, ballooning degeneration and fibrosis). These changes were associated with marked alterations in associated gene expression pathways implicated in NASH and development of fibrosis. The mouse models are also suitable for pharmacological intervention studies, with a paired baseline liver biopsy procedure enabling individual disease stage before a repeated dosing period as is customary in NASH preclinical studies. Whereas all mice experienced slight weight loss following the biopsy, they returned to a weight stable state within one week moreover DIO-NASH and ob/ob-NASH sustained hepatomegaly, hepatic steatosis, inflammation, ballooning degeneration and fibrosis following repeated dosing intervention for a total of 8 wk.

DIO-NASH and ob/ob-NASH mice developed key hallmarks of fibrotic NASH including marked hepatosteatosis with evident inflammation and ballooning degeneration, as assessed by a clinical-derived histological NAS and fibrosis stage classification system developed by Kleiner et al.[20]. This is in line with recent findings by Clapper et al.[6] and Honda et al.[24] in C57 AMLN mice, thus supporting the wild-type C57 DIO-NASH mouse as a suitable preclinical model for diet-induced obesity and NASH. In addition, the genetically obese ob/ob mouse model was also recently demonstrated to exhibit fibrotic NASH when fed AMLN diet[11,25]. In the leptin-deficient model superimposing the NASH diet high in trans-fat, fructose and cholesterol represents a “second hit” in development of preclinical NASH. The present study demonstrates that the NAS

**Figure 4** Histological assessment of non-alcoholic fatty liver disease activity score and liver lipid at study end. Representative H and E stained sections from; lean chow (A), ob/ob chow (B), DIO-NASH (C) and ob/ob NASH (D) mouse models. NAFLD activity score (steatosis, inflammation and ballooning degeneration) performed by a blinded pathologist at study end (E), and quantitatively image analysis of steatosis (% area) from H and E staining using visiomorph software (F). Macrovesicular steatosis indicated by arrowheads, microvesicular steatosis indicated by short black arrows, inflammation indicated by short blue arrows, ballooning degeneration indicated by long black arrows. *P* < 0.05, *P* < 0.01, *P* < 0.001. The results are presented as mean ± SEM. Lean chow (n = 9), DIO-NASH (n = 12), ob/ob chow (n = 8), ob/ob NASH (n = 10). NASH: Nonalcoholic steatohepatitis; NAFLD: Nonalcoholic fatty liver disease; SEM: Standard error of the mean.
and fibrosis stage can also be integrated in analyses of the ob/ob-NASH mouse - and in conjunction with the excessive accumulation of hepatic lipids and collagen content - introduces an accelerated and aggressive diet-induced NASH phenotype relative to the C57 DIO-NASH model.

In accordance with histological observations of hepatic inflammation, mRNA analyses revealed within inflammatory pathways that Toll-like receptors and downstream pro-inflammatory effectors (e.g., Il1b, MCP-1) were markedly upregulated after the diet-induction period in DIO-NASH and ob/ob-NASH. In line with previous findings in diet-induced NASH mouse models, we observed increased expression of TLR4, a key receptor in fibrogenic development as demonstrated in high-fat diet-induced TLR4 knockout mice, and bile duct ligation models. In addition, TLR4 KO in ob/ob mice was protective against NASH development as evinced by reduced NAS compared to regular ob/ob mice.

Interestingly, we observed higher expression levels of four additional TLRs: TLR7, TLR8, TLR12 and TLR13, which could be of relevance in future elucidation of the pathogenesis of NASH and for pharmacological intervention.

CCR2 mRNA levels were also increased in ob/ob-NASH mice. CCR2 has been implicated in the development of liver fibrosis, with Ccr2−/− mice showing reduced fibrosis following bile duct ligation or CCl4 exposure. CCR2 is a functional receptor for MCP-1, and is involved in the migration of macrophages during obesity. Together, the impact on TLR signaling and macrophage abundance indicates an accelerated inflammatory NASH...
Nonalcoholic steatohepatitis (NASH) is an emerging liver disease with increasing prevalence. There are currently no pharmacological agents specifically approved for the treatment of NASH and disease management is consequently focused on the correction of underlying risk factors such as obesity, insulin resistance and dyslipidemia.

**Research frontiers**

The lack of approved therapeutics has to some degree been attributed to the failure of animal models to faithfully represent the clinical condition (e.g., disease progression and metabolic background) and the way NASH is assessed clinically (paired biopsies and validated histological methods). Hence, novel diet-induced NASH models that develop the appropriate metabolic phenotype with improved liver sampling methods are highly desirable as a preclinical platform for exploring novel NASH treatments.

**Innovations and breakthroughs**

The authors describe and characterize a wild-type C57 and a genetically (ob/ob) obese diet-induced mouse model of NASH and confirm previous findings demonstrating key hallmarks of metabolic deregulation and fibrotic NASH using biochemical, histological and gene expression endpoints. Notably, a liver biopsy-confirmed and clinically-derived histological NASH scoring and fibrosis staging are being performed in ob/ob mice, which the authors are the first to report. Finally, the utility of the diet-induced NASH mouse models for pharmacological investigations is being demonstrated by performing a chronic intervention period with repeated dosing following a baseline liver biopsy procedure.

**Applications**

A baseline liver biopsy performed after diet-induction allows for individual disease staging for stratification and randomization into study groups and for evaluation of novel NASH therapeutics.

**Peer-review**

The results of this study demonstrated a useful animal model for evaluation the disease progression and treatment of NASH. The data were appropriately presented and interpreted. The manuscript was well prepared.
